

# Abstract

Targeted alpha therapies using actinium-225 ( $^{225}\text{Ac}$ ,  $t_{1/2} = 9.9$  d) have shown an ability to treat advanced metastatic disease, despite the insufficient availability of this radionuclide that limits their development. Radiation dosimetry for  $^{225}\text{Ac}$ -radiopharmaceuticals is also complicated by multiple nuclides in the  $^{225}\text{Ac}$  decay chain. This work describes efforts to produce  $^{225}\text{Ac}$  and use multi-nuclide SPECT imaging to individually measure the biodistribution of  $^{225}\text{Ac}$  progeny,  $^{221}\text{Fr}$  and  $^{213}\text{Bi}$ . Initial  $^{225}\text{Ac}$  production used  $^{\text{Nat}}\text{U}$ -spallation-produced and mass-separated ion beams to produce up to 8.6 MBq of  $^{225}\text{Ra}$ , an  $^{225}\text{Ac}$  parent, and up to 18 MBq of  $^{225}\text{Ac}$ . This material was used to characterize performance of  $^{225}\text{Ac}$  decay chain imaging on a microSPECT/PET/CT scanner in terms of contrast recovery, spatial resolution, and noise. Efforts to produce larger  $^{225}\text{Ac}$  quantities used the proton spallation of thorium with focus on using  $^{225}\text{Ra}/^{225}\text{Ac}$  generators to provide an Ac product with reduced  $^{227}\text{Ac}$  ( $t_{1/2} = 21.8$  y) content, a nuclide with economically prohibitive and low limits on waste disposal. Targets containing Th metal foils were irradiated for approximately 36 hours with a 72  $\mu\text{A}$  proton beam, producing  $(521 \pm 18)$  MBq of  $^{225}\text{Ac}$  and  $(91 \pm 14)$  MBq of  $^{225}\text{Ra}$ . These irradiations enabled  $^{232}\text{Th}(p,x)$  cross sections measurements at 438 MeV for  $^{225}\text{Ac}$ ,  $^{225}\text{Ra}$ , and  $^{227}\text{Ac}$ :  $(13.3 \pm 1.2)$  mb,  $(4.2 \pm 0.4)$  mb, and  $(17.7 \pm 1.7)$  mb, respectively. 35 other cross sections have been measured and compared to FLUKA simulations; measured and calculated values generally agree within a factor of 2. Ac was separated from irradiated thorium and co-produced radioactive spallation and fission products using a thorium peroxide precipitation followed by cation exchange and extraction chromatography. Tracer studies demonstrated this method's ability to separate Ac from most other elements, providing a directly produced Ac product ( $^{227,225}\text{Ac}^\dagger$ ) with measured  $^{227}\text{Ac}$  content of  $(0.15 \pm 0.04)\%$ . The second, indirectly produced Ac product ( $^{225}\text{Ac}^*$ ) with  $^{227}\text{Ac}$  content of  $<7.5 \times 10^{-5}\%$  is obtained by repeating the final extraction chromatography step with the  $^{225}\text{Ra}$ -containing fraction. The  $^{225}\text{Ra}$ -derived  $^{225}\text{Ac}^*$  showed similar or improved quality compared to the initial, directly produced  $^{227,225}\text{Ac}^\dagger$  product in terms of chemical purity and radiolabeling capability.
